First draft: August 19, 2013
This draft: October 6, 2013

Abstract

This paper employs an approximation that makes a nonlinear term structure model extremely tractable for analysis of an economy operating near the zero lower bound for interest rates. We show that such a model offers an excellent description of the data and can be used to summarize the macroeconomic effects of unconventional monetary policy at the zero lower bound. Our estimates imply that the efforts by the Federal Reserve to stimulate the economy since 2009 succeeded in making the unemployment rate in May 2013 0.23% lower than it otherwise would have been.

Keywords: monetary policy, zero lower bound, unemployment, shadow rate, dynamic term structure model

JEL classification codes: E43, E52

1 Introduction

Historically the Federal Reserve has used the federal funds rate as the primary instrument of monetary policy, lowering the rate to provide more stimulus and raising it to slow economic activity and control inflation. But since December 2008, the fed funds rate has been near zero, so that lowering it further to produce more stimulus has not been an option. Consequently, the Fed has relied on unconventional policy tools such as large-scale asset purchases and forward guidance to try to affect long-term interest rates and influence the economy. Assessing the impact of these measures or summarizing the overall stance of monetary policy in the new environment has proven to be a big challenge. Previous efforts include Gagnon, Raskin, Remache, and Sack(2011) Hamilton and Wu(2012) Krishnamurthy and Vissing-Jorgensen(2011) D’Amico and King(2013) Wright(2012) Bauer and Rudebusch(2012) and Swanson and Williams(2013). However, these papers only focused on measuring the effects on the yield curve. Our interest in this paper is the more important goal of assessing the effects on the real economy.

A related challenge has been to describe the relations between the yields on assets of different maturities in the new environment. The workhorse model in the term structure literature has been the Gaussian affine term structure model (GATSM); for surveys, see Piazzesi(2010) Duffee(2012) Gürkaynak and Wright(2012) and Diebold and Rudebusch(2013). However, because this model is linear in Gaussian factors, it potentially allows nominal interest rates to go negative and faces real difficulties in the zero lower bound (ZLB) environment. One approach that could potentially prove helpful for both measuring the effects of policy and describing the relations between different yields is the shadow rate term structure model (SRTSM) first proposed by Black(1995). This model posits the existence of a shadow interest rate that is linear in Gaussian factors, with the actual short-term interest rate the maximum of the shadow rate and zero. However, the fact that an analytical solution to this model is known only in the case of a one-factor model makes using it more challenging.

In this paper we propose a simple analytical representation for bond prices in the SRTSM.
that provides an excellent approximation and is extremely tractable for analysis and empirical implementation. It can be applied directly to discrete-time data to gain immediate insights into the nature of the SRTSM predictions. We demonstrate that this model offers an excellent empirical description of the recent behavior of interest rates. More importantly, we show using a simple factor-augmented vector autoregression (FAVAR) that the shadow rate calculated by our model exhibits similar dynamic correlations with macro variables of interest in the period since 2009 as the fed funds rate did in data prior to the Great Recession. This result gives us a tool for measuring the effects of monetary policy under the ZLB, using either historical estimates based on the fed funds rate or less precisely measured estimates inferred solely from the new data for the shadow rate alone. We show that the Fed has used unconventional policy measures to successfully lower the shadow rate. Our estimates imply that the Fed’s efforts to stimulate the economy since 2009 have succeeded in lowering the unemployment rate by 0.23% relative to where it would have been in the absence of these measures.

The SRTSM has been used to describe the recent behavior of interest rates and monetary policy by [Kim and Singleton(2012)] and [Bauer and Rudebusch(2013)], but these authors relied on simulation methods to estimate and study the model. [Krippner(2013)] proposed a continuous-time analog to our solution, where he added a call option feature to derive the solution. [Ichiue and Ueno(2013)] derived similar approximate bond prices by ignoring Jensen’s inequality. Both derivations are in continuous time, which requires numerical integration when applied to discrete-time data.

Our paper also contributes to the recent discussion on the usefulness of the shadow rate as a measure for the monetary policy stance. [Christensen and Rudebusch(2013)] and [Bauer and Rudebusch(2013)] pointed out that the estimated shadow rate varied across different models. [Bullard(2012)] and [Krippner(2012)] advocated the potential of the shadow rate to describe the monetary policy stance. Our results provide further empirical evidence to support the latter view, and demonstrate that the shadow rate is a powerful tool to summarize information at
the ZLB.

The rest of the paper proceeds as follows. Section 2 describes the SRTSM. Section 3 proposes a new measure for monetary policy at the ZLB and demonstrates its advantage over the effective federal funds rate. Section 4 summarizes the implication of unconventional monetary policy on the macroeconomy using historical data from 1960 to 2013, and Section 5 zooms in on the ZLB period. Section 6 concludes.

2 Shadow rate term structure model

2.1 Shadow rate

Similar to Black(1995), we assume that the short term interest rate is the maximum of the shadow rate \( s_t \) and a lower bound \( r \):

\[
r_t = \max(r, s_t).
\]  

(1)

If the shadow rate \( s_t \) is greater than the lower bound, then \( s_t \) is the short rate. Note that when the lower bound is binding, the shadow rate contains more information about the current state of the economy than does the short rate itself. Since the end of 2009, the Federal Reserve has paid interest on reserves at an annual interest rate of 0.25%, proposing the choice of \( r = 0.25 \).

2.2 Factor dynamics

We assume that the shadow rate \( s_t \) is an affine function of some state variables \( X_t \),

\[
s_t = \delta_0 + \delta'_1 X_t.
\]  

(2)
The state variables follow a first order vector autoregressive process (VAR(1)) under the physical measure (P):

\[ X_{t+1} = \mu + \rho X_t + \Sigma \varepsilon_{t+1}, \quad \varepsilon_{t+1} \sim N(0, I). \]  

(3)

The log stochastic discount factor is essentially affine as in [Duffee(2002)]

\[ M_{t+1} = \exp \left( -r_t - \frac{1}{2} \lambda_t' \lambda_t - \lambda_t' \varepsilon_{t+1} \right), \]  

(4)

where the price of risk \( \lambda_t \) is linear in the factors

\[ \lambda_t = \lambda_0 + \lambda_1 X_t. \]

This implies that the risk neutral measure (Q) dynamics for the factors are also a VAR(1):

\[ X_{t+1} = \mu^Q + \rho^Q X_t + \Sigma^Q \varepsilon_{t+1}^Q, \quad \varepsilon_{t+1}^Q \sim N(0, I). \]  

(5)

The parameters under the P and Q measures are related as follows:

\[ \mu - \mu^Q = \Sigma \lambda_0, \]

\[ \rho - \rho^Q = \Sigma \lambda_1. \]

2.3 Forward rates

Equation (1) introduces non-linearity into an otherwise linear system. A closed-form pricing formula for the SRTSM described in Sections 2.1 - 2.2 is not available beyond one factor. In this section, we propose an analytical approximation for the forward rate in the SRTSM, making the otherwise complicated model extremely tractable. Our formula is simple and intuitive, and we will compare it to the solution in a Gaussian model in Section 2.4 to gain
some intuition. A simulation study in Section 2.6 demonstrates that the error associated with our approximation is only a few basis points.

Define $f_{n,n+1,t}$ as the forward rate at time $t$ for a loan starting at $t+n$ and maturing at $t+n+1$. The forward rate in the SRTSM described in equations (1) to (5) can be approximated by

$$f_{n,n+1,t}^{SR} = r + \sigma^Q_n g \left( \frac{a_n + b'_n X_t - r}{\sigma_n^Q} \right), \quad (6)$$

where $(\sigma^Q_n)^2 \equiv Var^Q_t(s_{t+n})$. The function $g(.)$ is defined as $g(z) \equiv z\Phi(z) + \phi(z)$, where $\Phi(.)$ and $\phi(.)$ are the cumulative distribution function (CDF) and probability density function of a standard normal distribution. The expressions for $a_n$ and $b_n$ as well as the derivation are in Appendix A. Equation (6) implies time-varying factor loadings:

$$\frac{\partial f_{n,n+1,t}^{SR}}{\partial X'_t} = \Phi \left( \frac{a_n + b'_n X_t - r}{\sigma_n^Q} \right) \times b'_n. \quad (7)$$

To our knowledge, we are the first in the literature to propose an analytical approximation for the forward rate in the SRTSM that can be applied to discrete-time data directly. For example, Bauer and Rudebusch (2013) used a simulation-based method, and simulated hundreds of draws every time the numerical optimizer evaluated the objective function. Krippner (2013) proposed an approximation for the instantaneous forward rate in continuous-time. To apply his formula to the one-month ahead forward rate in the data, a researcher needs to numerically integrate the instantaneous forward rate over that month. Conversely, our discrete-time formula can be applied directly to the one-month ahead forward rate. Besides the time cost involved in simulation and numerical integration, there is also some simulation error associated with these procedures.
2.4 Relation to Gaussian models

If we replace equation (1) with

\[ r_t = s_t, \]

the SRTSM becomes a GATSM, the benchmark model in the term structure literature. The forward rate in the GATSM is an affine function of the factors:

\[ f_{n,n+1,t}^{GA} = a_n + b'_n X_t, \tag{8} \]

where \( a_n \) and \( b_n \) are the same as in equation (6), and the derivation is in Appendix A.

The GATSM is extremely popular in the literature, because its linear Gaussian feature makes it more tractable than its competitors. However, in a GATSM, negative interest rates are permissible. This is undesirable, and it is more relevant and problematic when the economy gets closer to the ZLB. Now the question becomes: when the economy is normal, is the GATSM a close description of the yield curve? Is this potential issue outweighed by its benefits?

The difference between equations (6) and (8) is that equation (6) adds non-linearity through the function \( g(.) \). To appreciate this difference better, let us first take a closer look at the function \( g(.) \). We plot \( g(z) \) as a function of \( z \) in Figure 1 together with the 45 degree line. It is a non-linear and increasing function in \( z \). It is indistinguishable from the 45 degree line for inputs greater than 2, and is practically zero for \( z \) less than \(-2\).

The fact that \( g(z) \approx z \) for \( z > 2 \) demonstrates that the GATSM is a simple and close approximation for the SRTSM, when the economy is away from the ZLB. It justifies the intuition people have about the GATSM. The intuition is simple: when the current short rate is sufficiently positive, the expected future short rate will most likely stay positive, because of the highly persistent feature of the data. In this scenario, the lower bound introduced by equation (1) becomes irrelevant.
In contrast to equation (7), the factor loadings in the GATSM are constant as usual:

\[
\frac{\partial f_{GATSM}}{\partial X_t} = b'_n.
\]  

(9)

Equations (7) and (9) provide a nice contrast, and help us to better appreciate the difference between the GATSM and SRTSM. Besides the \( b'_n \) term in the GATSM, the SRTSM has an additional term. This additional term is between 0 and 1, and depends on where the economy is expected to be in the future. If the economy is expected to be far away from the lower bound, the factor loadings are practically \( b'_n \). But when the economy is close to the ZLB, the factor loadings are attenuated by the first term. The factor loadings are essentially zero and the forward rate does not respond to any news when we expect the economy to stay at the ZLB for a very long period of time.

\[\text{2.5 Estimation}\]

**State space representation for the SRTSM** The SRTSM can be written in the form of a nonlinear state space model. The transition equation for the state variables is equation (3). From equation (6), the measurement equation relates the observed forward rate \( f_{SRTSM} \) to the factors as follows:

\[
f_{SRTSM} = \tau + \sigma_n g \left( a_n + b'_n X_t - \tau \right) + \eta_{SR}^{nt},
\]

(10)

where the measurement error \( \eta_{SR}^{nt} \) is i.i.d. normal, \( \eta_{SR}^{nt} \sim N(0, \omega_{SR}) \). The observation equation is not linear in the factors, due to non-linearity of the function \( g(\cdot) \). We use the extended Kalman filter for estimation, which applies the Kalman filter by linearizing the nonlinear function \( g(\cdot) \) around the current estimates. See Appendix B for details.

The extended Kalman filter is extremely easy to apply due to the closed-form formula in equation (6). We take the observation equation (10) directly to data without any further numerical approximation, necessary for pricing formula derived in the continuous time.
The likelihood surface behaves similarly to a Gaussian model, because the function $g(.)$ is monotonically increasing. These features together make our formula very appealing.

**State space representation for the GATSM** For the GATSM described in Section 2.4 equation (3) is still the transition equation. Equation (8) implies the measurement equation:

$$f_{n,n+1,t}^o = a_n + b'_n X_t + \eta_{nt}^{GA}. \tag{11}$$

with $\eta_{nt}^{GA} \sim N(0,\omega_{GA})$. We apply the Kalman filter for the GATSM, because it is a linear Gaussian state space model. See Appendix B for details.

**Data** We construct one-month forward rates for maturities of 3 and 6 months, 1, 2, 5, 7 and 10 years from the Gü rkaynak, Sack, and Wright (2007) dataset, using observations at the end of the month. Our sample spans from January 1990 to June 2013. \footnote{Starting the sample from 1990 is standard in the GATSM literature, see Wright(2011) and Bauer, Rudebusch, and Wu(2012) for examples.} We plot the time series of these forward rates in Figure 2. In December 2008, the Federal Open Market Committee (FOMC) lowered the target range for the federal funds rate to 0 to 25 basis points. We refer to the period from January 2009 to the end of the sample as the ZLB period, and highlight with shading. For this period, forward rates of shorter maturities are essentially stuck at zero, and do not display meaningful variation. Forward rates with longer maturities are still far away from the lower bound, and display significant variation.

**Normalization** The consensus in the term structure literature is that three factors are sufficient to account for almost all of the cross-sectional variation in yields. Therefore, we follow the common practice, and focus our discussions on three factor models. The collection of parameters we estimate include $(\mu, \mu^Q, \rho, \rho^Q, \Sigma, \delta_0, \delta_1)$. For identification, we impose normalizing restrictions on the Q parameters similar to Joslin, Singleton, and Zhu(2011) and \footnote{All of our main results relating to the macroeconomy, from Section 3 onward, are robust to two-factor models. But for the term structure models themselves, two-factor models perform worse than three-factor models in terms of model comparison.}
Hamilton and Wu (forthcoming) (i) $\delta_1 = [1, 1, 0]'$; (ii) $\mu^Q = 0$; (iii) $\rho^Q$ is in real Jordan form with eigenvalues in descending order; and (iv) $\Sigma$ is lower triangular.

Repeated eigenvalues Estimation assuming that $\rho^Q$ has three distinct eigenvalues produces two smaller eigenvalues almost identical to each other, with the difference in the order of $10^{-3}$. Creal and Wu (2013) have documented a similar observation using a different dataset and a different model. We use a representation that imposes repeated eigenvalues and the real Jordan form is

$$
\rho^Q = \begin{bmatrix}
\rho_1^Q & 0 & 0 \\
0 & \rho_2^Q & 1 \\
0 & 0 & \rho_2^Q
\end{bmatrix}.
$$

Model comparison Maximum likelihood estimates, robust standard errors (See Hamilton (1994) p. 145), and log likelihood values are reported in Table 1. The log likelihood value is 750.29 for the GATSM, and 850.22 for the SRTSM. Both models have the same number of parameters. Any information criterion (e.g. AIC and BIC) would prefer the SRTSM. The superior performance of the SRTSM comes from its ability to fit the short end of the forward curve when the lower bound binds. In Figure 3, we plot average observed (red dots) and fitted (blue curves) forward curves in 2012. The left panel illustrates that the SRTSM fitted forward curve flattens at the short end, which is consistent with the feature of the data. That is because the $g(.)$ function is very close to zero when the input is sufficiently negative. In contrast, the GATSM in the right panel has trouble fitting the short end. Instead of having a flat short end as the data suggest, the GATSM generates too much curvature. That is the only way it can approximate behavior at the ZLB.

As demonstrated in equation (2.4), the GATSM is a good approximation for the SRTSM when forward rates are sufficiently higher than the lower bound. We illustrate this property using the following numerical example. When both models are estimated over the period
of January 1990 to December 1999, the maximum log likelihood is 475.71 for the SRTSM, and 476.69 for the GATSM. The slight difference in the likelihood comes from the linear approximation of the extended Kalman filter.

2.6 Approximation error

An alternative to equation (6) to compute forward rates or yields is simulation. In Table 2, we compare forward rates and yields implied by equation (6) and by an average of 10 million simulated paths to measure the size of the approximation error of equation (6). The details of simulation are explained in Table 2. The approximation errors grow with the time to maturity for both forward rates and yields. We focus on the longest end to report the worst case scenario. The average absolute approximation error of the 24 Januaries between 1990 and 2013 for the 10-year ahead forward rate is 2.3 basis points, about 0.36% of the average forward rate for this period (6.37%). The average number is 0.78 basis points for the 10 year yield with an average level of 5.29%. The ratio is 0.14%. The approximation errors for long term forward rates are larger than those for yields, because yields factor in the smaller approximation errors of short term and medium term forward rates. Regardless, the approximation errors are at most a few basis points, orders of magnitudes smaller than the levels of interest rates.

As a rough comparison, Christensen and Rudebusch (2013) calculated the approximation error of Krippner (2013)'s formula with Japanese data from 1995 to 2013. Their number is 2.25 basis points for the 10 year yield, while the average yield is less than 2%, an approximation error which is 1.1% of its level. The approximation errors in Table 2 contain simulation errors. With the large number of draws (10 million), the simulation errors are negligible. We repeat the same comparison for the GATSM with the same parameters and state variables. Because the analytical formula for the GATSM in equation (8) is exact, the difference between the analytical formula and simulation is purely simulation error. The average absolute simulation errors are 0.1 basis points for forward rates and 0.04 for yields.
3 Policy rate

The effective federal funds rate has served as the conventional policy rate to measure the monetary policy stance in the literature, and provided the basis for most empirical studies of the interaction between monetary policy and the economy. However, since 2009, the effective federal funds rate has been stuck at the lower bound, and no longer conveys any information due to its lack of variability. How do we summarize the effects of monetary policy in this situation? More importantly, what should economists use to measure the entire history of monetary policy when the short rate exits the ZLB and researchers include this period in their study? We aim to bridge this gap by proposing a new policy rate consistent across both the non-ZLB and ZLB periods. The shadow rate from the SRTSM is a natural candidate. We construct the new policy rate $s_{it}$ by splicing together the effective federal funds rate before the ZLB and the estimated shadow rate at the ZLB. This combination makes the most use out of both series. In Sections 3.2 and 5.1 we will elaborate on how the information summarized in the shadow rate is relevant for the economy.

We plot the model implied shadow rate (in blue) and the effective federal funds rate (in green) in Figure 4. Before 2009, the ZLB was not binding, the model implied short rate was equal to the shadow rate. The difference between the two lines in Figure 4 reflects measurement error, in units of basis points. The two rates have diverged since 2009. The effective federal funds rate has been stuck at the ZLB. In contrast, the shadow rate has become negative and still displays meaningful variation.

3.1 Factor augmented vector autoregression

We use the FAVAR model proposed by Bernanke, Boivin, and Eliasz (2005) to study the effects of monetary policy. The basic idea is to compactly summarize the rich information contained in a large set of economic variables $Y_t^m$ using a low-dimensional vector of factors $x_t^m$. This model allows us to study monetary policy’s impact on any macroeconomic variable
of interest. The factor structure also ensures that the parameter space does not explode.

Model Following Bernanke, Boivin, and Eliasz (2005), we use 3 factors, and assume that the factors $x_t^m$ and the policy rate $s_t^o$ jointly follow a VAR(13):

$$
\begin{bmatrix}
  x_t^m \\
  s_t^o
\end{bmatrix}
 =
\begin{bmatrix}
  \mu_x \\
  \mu_s
\end{bmatrix}
 +
\rho^m
\begin{bmatrix}
  X_{t-1}^m \\
  S_{t-1}^o
\end{bmatrix}
 +
\Sigma^m
\begin{bmatrix}
  \varepsilon_t^m \\
  \varepsilon_{t}^{MP}
\end{bmatrix},
\begin{bmatrix}
  \varepsilon_t^m \\
  \varepsilon_{t}^{MP}
\end{bmatrix}
 \sim N(0, I),
$$

(12)

where we summarize the current value of $x_t^m$ (or $s_t^o$) and its 12 lags using a capital letter to capture the state of the economy, $X_t^m = [x_t^{m'}, x_{t-1}^{m'}, ..., x_{t-12}^{m'}]'$, (and $S_t^o = [s_t^o, s_{t-1}^o, ..., s_{t-12}^o]'$). Constants $\mu_x$ and $\mu_s$ are the intercepts, and $\rho^m$ is the autoregressive coefficient. The matrix $\Sigma^m$ is the cholesky decomposition of the covariance matrix. The monetary policy shock is $\varepsilon_{t}^{MP}$. We identify the monetary policy shock through the recursiveness assumption as in Bernanke, Boivin, and Eliasz (2005); for details see Appendix C. Observed macroeconomic variables load on the macroeconomic factors and policy rate as follows:

$$
Y_t^m = a_m + b_x x_t^m + b_s s_t^o + \eta_t^m, \quad \eta_t^m \sim N(0, \Omega),
$$

(13)

where $a_m$ is the intercept, and $b_x$ and $b_s$ are factor loadings.

Data Similar to Bernanke, Boivin, and Eliasz (2005), $Y_t^m$ consists of a balanced panel of 97 macroeconomic time series from the Global Insight Basic Economics, and our data spans from January 1960 to May 2013.\footnote{Global Insight Basic Economics does not maintain all 120 series used in Bernanke, Boivin, and Eliasz (2005). Only 97 series are available from January 1960 to May 2013. The main results from Bernanke, Boivin, and Eliasz (2005) using their 120 series from January 1959 to August 2001 can be replicated by using the 97 series available for longer sample from January 1960 to August 2001.} We have a total of $T = 628$ observations. We apply the same data transformations as in the original paper to ensure stationarity. See Table 3 for detailed data description.
**Estimation**  First, we extract the first three principal components of the observed macroeconomic variables over the period January 1960 to May 2013, and take the part that is orthogonal to the policy rate as the macroeconomic factors. Then, we estimate equation (13) by ordinary least squares (OLS). See Appendix C for details. Next, we estimate equations (12) by OLS.

**Macroeconomic variables and factors**  The loadings of the 97 macro variables on the factors are plotted in Figure 5. Real activity measures load heavily on factor 1, price level indexes load more on factor 2, and factor 3 contributes primarily to employment and prices. For the contemporaneous regression in equation (13), more than one third of the variables have an $R^2$ above 60%, which confirms the three-factor structure. Besides the policy rate, we focus on the following five macroeconomic variables: industrial production, consumer price index, capacity utilization, unemployment rate and housing starts. They represent the three factors, and cover both real activities and price levels. The $R^2$s for these macroeconomic variables are 74%, 89%, 65%, 64% and 66% respectively.

### 3.2 Measures of monetary policy

The natural question is whether the shadow rate could be used in place of the fed funds rate to describe the stance and effects of monetary policy under the ZLB. We first approach this using a formal hypothesis test—can we reject the hypothesis that the parameters relating the shadow rate to macroeconomic variables of interest under the ZLB are the same as those that related the fed funds rate to those variables in normal times?

We begin this exercise by acknowledging that we do not attempt to model the Great Recession in our paper, because it was associated with some extreme financial events and monetary policy responses. For example, [Ng and Wright(2013)](#) provide some empirical evidence to show that the Great Recession is different in nature from other post-war recessions. Instead, we are interested in the behavior of monetary policy and the economy in the period
following the Great Recession, when policy returned to a new normal that ended up being implemented through the traditional 6-week FOMC calendar but using the unconventional tools of large scale asset purchases and forward guidance. We investigate whether a summary of this new normal based on our derived shadow rate shows similar dynamic correlations as did the fed funds rate in the period prior to the Great Recession.

We modify the first block in equation (12) by allowing the coefficient in front of the lagged policy rate to be different before, during, and after the Great Recession, and we also allow for different measures of the policy rate:

\[ x_t^m = \mu_x + \rho_{xx} X_{t-1}^m \]
\[ + \ 1 \ (t<\text{December 2007}) \rho_{xs,1}^m \tilde{s}_t^o \]
\[ + \ 1 \ (\text{December 2007} \leq t \leq \text{June 2009}) \rho_{xs,2}^m \tilde{s}_t^o \]
\[ + \ 1 \ (t>\text{June 2009}) \rho_{xs,3}^m \tilde{s}_t^o \]
\[ + \ \Sigma_{xx} \epsilon_t^m \]  

(14)

where \( \tilde{s}_t^o = [s_t^o, \tilde{s}_{t-1}^o, ..., \tilde{s}_{t-12}^o]' \), and \( \tilde{s}_t^o \) is represented by one of two different measures: our new policy rate \( \tilde{s}_t^o = s_t^o \), or the effective federal funds rate \( \tilde{s}_t^o = r_t^o \). The null hypothesis is that the coefficient \( \rho_{xs}^m \) is the same before and after the Great Recession:

\[ H_0 : \rho_{xs,1}^m = \rho_{xs,3}^m. \]

We construct the likelihood ratio statistic as follows (see Hamilton(1994) p. 297):

\[ (T - k)(\log|\Sigma_R^x \Sigma_R^x'| - \log|\Sigma_U^x \Sigma_U^x'|), \]

where \( T \) is the sample size, \( k \) is the number of regressors on the right hand side of equation (14), \( \Sigma_R^x \Sigma_R^x' \) is the estimated covariance matrix, and \( \Sigma_U^x \Sigma_U^x' \) is the estimated covariance matrix with the restriction imposed by the null hypothesis.
The likelihood ratio statistic has an asymptotic \( \chi^2 \) distribution with 39 degrees of freedom. The \( p \)-value is 0.19 for our policy rate \( s_0^p \). We fail to reject the null hypothesis at any conventional significance level. This is consistent with the claim that our proposed policy rate impacts the macroeconomy the same way at the ZLB as before. If we use the effective federal funds rate instead, the \( p \)-value is 0.0015, and we would reject the null hypothesis at any conventional significance level. Our results show that there is a structural break if one tries to use the conventional monetary policy rate. In summary, our policy rate exhibits similar dynamic relations to key macro variables before and after the Great Recession, and appears to capture meaningful information missing from the effective federal funds rate after the economy reached the ZLB.

4 Macroeconomic implications

The literature has thus far focused on the effects of unconventional monetary policy on the yield curve. Taking a bold step away from the literature, we attempt to answer some more fundamental questions: what is the impact of the new unconventional policy tools on the real economy? Is the Fed able to achieve its stated goal of lowering the unemployment rate?

4.1 Historical decomposition

After the Great Recession the Federal Reserve implemented a sequence of unconventional monetary policy measures including quantitative easing and forward guidance. What has been the net effect of the various unconventional policy measures adopted by the Federal Reserve? We can answer this question with a historical decomposition by singling out the contribution of monetary policy for this period.

The basic idea is that we can write each variable in equation (12) as a sum of past shocks and its initial condition. Specifically, the contribution of monetary policy shocks between
\[ t_1, t_2 \] to an individual economic variables \( Y_{t,i}^{m} \) can be summarized by

\[
\sum_{\tau=t_1}^{t_2} \Psi_{t-\tau}^{MP,i} \epsilon_{\tau}^{MP},
\]

where \( \Psi_{j}^{MP,i} \) is the impulse response

\[
\Psi_{j}^{MP,i} = \frac{\partial Y_{t+j}^{m,i}}{\partial \epsilon_{t}^{MP}} = b_{x,i} \frac{\partial x_{t+j}^{m}}{\partial \epsilon_{t}^{MP}} + b_{s,i} \frac{\partial s_{t+j}^{o}}{\partial \epsilon_{t}^{MP}},
\]

for variable \( i \) after \( j \) periods in response to a one unit shock in \( \epsilon_{t}^{MP} \), and the derivatives on the right hand side are the impulse responses from a standard VAR.

In Figure 6, we plot the observed time series for the six variables in blue, and counterfactual paths in red dashed lines for an alternative world where all the monetary policy shocks at the ZLB were zero. In the top left panel, we show the difference between the realized and counterfactual policy rates. Without unconventional monetary policy, the policy rate would have been about 0 in 2012, whereas the actual policy rate then was about -1.5%. On average, the Fed’s actions have reduced the policy rate by 0.32% between 2011 and 2013. These contrasts indicate that unconventional monetary policy has been actively lowering the policy rate, and the Federal Reserve has employed an expansionary monetary policy since 2011.

Next consider implications for the real economy. In the absence of expansionary monetary policy, in May 2013, the industrial production index would have been 96.7 rather than 98.7, and capacity utilization would be 0.6% lower than what we observe. Housing starts would be 34,000 lower (880,000 vs. 914,000). Unemployment would be 0.23% higher at the 7.83% level rather than 7.6% in the data. These numbers suggests that unconventional monetary policy achieved its goal of stimulating the economy.

Interestingly, the accommodative monetary policy during this period have not boosted real activities at the cost of high inflation. Instead, monetary policy shocks have contributed to raising the consumer price index by 2. This result displays the price puzzle discussed in
One of the challenges for estimating potential policy effects on the basis of historical correlations is endogeneity because the dynamic correlation between the policy rate and macro variables may reflect the response of the Fed to the economic fundamentals through the Taylor rule. In this spirit, there are several alternative counterfactual scenarios with which we could compare. For example, we could shut down the Taylor rule channel, i.e. disallow the policy rate to react to the macro variables; or we could keep the policy rate a constant as an instrument of no monetary policy. Any of the alternative exercises generates larger numbers than the exercise we conducted. In this sense, we consider our estimates as a lower bound of the overall effects of unconventional monetary policy.

4.2 Impulse responses

What would happen to the unemployment rate one year later if the Fed decreases the policy rate by 25 basis points now? An impulse response function offers a way to think about questions as such by describing monetary policy’s dynamic impact on the economy.

We compute the impulse responses using equation (15) and plot them in Figure 7 for six economic variables (the policy rate, industrial production, consumer price index, capacity utilization, unemployment rate and housing starts) to a loosening monetary policy shock with a size of 25 basis points ($\Sigma_{w=1}^{m} MP_t = 25$ bp). The 90% confidence intervals are in the shaded areas.\footnote{Confidence intervals are constructed by bootstrapping.} With an expansionary monetary policy shock, real activity increases as expected: industrial production, capacity utilization and housing starts increase while the unemployment rate decreases. The impacts peak after about a year. Specifically, one year after a -25 basis-point shock to the policy rate, industrial production is 0.5% higher than its steady state level, capacity utilization increases by 0.2%, the unemployment rate decreases by 0.06%, and housing starts is 1.3% above its steady state level. After the peak, the effects die off slowly, and they are eventually gone in about 8 years.

\footnote{Examples include Sims(1992) and Eichenbaum(1992)}
5 Macroeconomic impact at the ZLB

The above measures assumed a constant structure before and after Great Depression. The ZLB period (July 2009 to May 2013) draws attention in its own right. Ideally, we want to repeat the FAVAR (13) exercise with the data only from the ZLB. However, with a sample size of 46 months, and the number of regressors being 52+1, we cannot estimate the 13-lag FAVAR due to multicollinearity. Instead, we use a 1-lag FAVAR to get some inference.

5.1 New vs. conventional policy rates

Consider first an attempt to estimate a first-order FAVAR for data since 2009 in which the effective fed funds rate is used as the policy rate. We plot impulse responses to an expansionary policy shock of 25 basis points in Figure 8. The turquoise lines are median responses, and 90% confidence intervals are in the turquoise areas. For comparison, we also plot the impulse responses for the full sample with our policy rate in blue. These are identical to the impulse responses presented in Figure 7. For the ZLB subsample, the impulse responses to a shock to the effective federal funds rate are associated with huge uncertainty, with the confidence intervals orders of magnitude bigger than those for the full sample. This indicates that the effective federal funds rate does not carry much information at the ZLB. The reason is simple: it is bounded by the lower bound, and does not display any meaningful variation. We can also see this from Figure 4.

By contrast, Figure 9 plots impulse-response functions in turquoise with our policy rate introduced in Section 3. Again, we compare them with full sample impulse responses in blue. Overall, the subsample impulse responses are qualitatively the same as those for the full sample. Specifically, an expansionary monetary policy shock boosts real economic activity. The impulse responses for the subsample and full sample also look quantitatively similar. The point estimates and confidence intervals have the same orders of magnitude. Therefore, at the ZLB, our new policy rate conveys important and economically meaningful
information; while the conventional policy rate gets stuck around zero.

5.2 Forward guidance

Since December 2008, the federal funds rate has been restricted by the ZLB. The conventional monetary policy is no longer effective, because the Federal Reserve cannot further decrease the federal funds rate below zero to boost the economy. Consequently, the central bank has resorted to a sequence of unconventional monetary policy tools. One prominent example is forward guidance, or central bank communications with the public about the future federal funds rate. In particular, forward guidance aims to lower the market’s expectation regarding the future short rate. Market expectations about future short rates feed back through the financial market to affect the current yield curve, especially at the longer end. Lower long term interest rates in turn stimulate aggregate demand. The Federal Reserve has made considerable use of forward guidance since the federal funds rate first hit the ZLB. In Table [4] we summarize a list of forward guidance quotes, when the Fed expected a different lift-off date or condition for the ZLB. Some of these dates overlap with Woodford(2012). The wording focuses either on (i) the length of the ZLB, or (ii) the target unemployment rate. Section [5.2.1] compares the length of the ZLB prescribed by forward guidance and the market’s expectation from our model. Section [5.2.2] studies the impact of forward guidance on the unemployment rate.

5.2.1 ZLB duration

One focus of forward guidance is for the Federal Reserve to implicitly or explicitly communicate with the general public about how long it intends to keep the federal funds rate near zero, as demonstrated in Table [4]. For example, in the earlier FOMC statements in late 2008 and early 2009, they used phrases such as “some time” and “an extended period”. Later on, starting from late 2011, the Federal Reserve decided to be more transparent and specific about forward guidance. In each statement, they unambiguously revised the date, on which
they expected the ZLB to end, according to the development of the overall economy.

Our model implies a closely related concept: ZLB duration. It measures the market’s perception of when the economy will finally escape from the ZLB. This is a random variable defined as

$$
\tau_t \equiv \inf \{ \tau_t \geq 0 | s_{t+\tau} \geq r \}.
$$

Thus $\tau_t$ represents how much time passes before the shadow rate first crosses the lower bound from below. At time $t$, $s_{t+\tau}$ is unknown. We simulate out $N = 10000$ paths of the future shadow rate given the information at time $t$. Every simulated path generates an estimate of $\tau_t$. Therefore, we have a distribution of $\tau_t$, and we take the median across $N$ simulations as our measure of the market’s expected ZLB duration.

We summarize the time series of the market’s expected ZLB duration in Figure 10 as the difference between the blue triangles and dashed 45 degree line. The duration increased since early 2009 and kept above the two-and-a-half-year level from late-2011 to mid-2013, when it plummeted to around one year and a half. We highlight four different months: August 2011, January 2012, September 2012 and June 2013. They correspond to those dates when the Fed explicitly spelled out the ZLB lift-off dates (see Table 4). On August 9, 2011, the Federal Reserve promised to keep the rate low “at least through mid-2013”. The market anticipated this development one month ahead. When the lift-off date was postponed to “at least through late 2014” on January 25, 2012, the market expected the ZLB to last another three years. The two expectations overlap each other. On September 13, 2012, the forward guidance further extended the lift-off date to “at least through mid-2015”, the market’s expected duration increased to three and a half years. On June 19, 2013, Federal Reserve Board Chairman Ben Bernanke expressed in a press conference the Federal Reserve’s plan to maintain accommodative monetary policy until 2015 based on the economic outlook at that time. Following his remarks, the market’s expected lift-off date jump right on top of

---

6 Similar to (Bauer and Rudebusch(2013)), we use the Q parameters for simulation, because (i) Q is the probability measure reflected in assets price, and (ii) Q parameters are estimated with much more precision than P parameters (see discussion in Creal and Wu(2013) for example).
Bernanke’s expectation.

Overall, evidence suggests that forward guidance and the market’s expectation align well. The market seems to adjust towards the Fed’s announcements ahead of time. For multiple occasions, the two expectations overlapped each other. In the next section, we will use the expected ZLB duration as a proxy for forward guidance, and study its impact on the real economy, especially the unemployment rate.

5.2.2 Impact on unemployment

We have demonstrated that forward guidance has achieved a great success in guiding the market’s expectation and influencing the yield curve. The ultimate question central bankers and economists care about is whether forward guidance is as successful in terms of its impact on the real economy, especially unemployment. We phrase this question in a FAVAR(1) framework with the expected ZLB duration measuring the monetary policy, and use this tool to study the transmission mechanism of forward guidance. For the macroeconomic factors, we keep them as they were. Figure 11 shows the impulse responses to a shock to expected ZLB duration of one year for the same set of variables. Overall, in response to an easing of monetary policy, the economy starts to expand. Most interestingly, a one year increase in the expected ZLB duration translates into a 0.25% decrease in the unemployment rate.

A simple calculation suggests that a one year increase in the expected ZLB duration has roughly the same effect on the macroeconomy as a 35 basis-point decrease in the policy rate. The visual comparison is in Figure 12 where the blue part is identical to Figure 11 and the turquoise portion is 35/25 times the turquoise in figure 9. Figure 12 suggests that in response to a one year shock to the expected ZLB duration, or a negative 35 basis-point shock to the policy rate, capacity utilization goes up by 0.6%, unemployment rate decreases by 0.25% and housing starts is about 5% over its steady state.
6 Conclusion

We have developed an analytical approximation for the forward rate in the SRTSM, making the otherwise complicated model extremely tractable. The approximation is an excellent description of the data especially when the economy is at the ZLB, with the approximation error being only a couple of basis points. We used the shadow rate from the SRTSM to construct a new measure for the monetary policy stance when the effective federal funds rate is bounded below by zero, and employed this measure to study unconventional monetary policy’s impact on the real economy. We have found that our policy rate impacts the real economy at the ZLB in a similar fashion as the effective federal funds rate did before the Great Recession. An expansionary monetary policy shock boosts the real economy. More specifically, at the ZLB, in response to a negative 35 basis-point shock to the policy rate, the unemployment rate decreases by 0.25%. This quantity is equivalent to a one year extension of the expected ZLB period, prescribed by forward guidance. Our historical decomposition has found that the efforts by the Federal Reserve to stimulate the economy since 2009 succeeded in making the unemployment rate in May 2013 0.23% lower than it otherwise would have been.

Appendix A  Approximation to Forward rates

Define

$$\bar{a}_n \equiv \delta_0 + \delta'_1 \left( \sum_{j=0}^{n-1} (\rho^Q)^j \right) \mu^Q,$$

$$a_n \equiv \bar{a}_n - \frac{1}{2} \delta'_1 \left( \sum_{j=0}^{n-1} (\rho^Q)^j \right) \Sigma \Sigma' \left( \sum_{j=0}^{n-1} (\rho^Q)^j \right)' \delta_1,$$

$$b'_n \equiv \delta'_1 (\rho^Q)^n.$$

Shadow rate  The shadow rate is affine in the state variables. Under the risk neutral measure, it is conditionally normally distributed. The conditional mean is

$$E_t^Q [s_{t+n}] = \bar{a}_n + b'_n X_t,$$

the conditional variance is

$$\text{Var}_t^Q [s_{t+n}] \equiv \left( \sigma^Q_n \right)^2 = \sum_{j=0}^{n-1} \delta'_1 (\rho^Q)^j \Sigma \Sigma' (\rho^Q)^j \delta_1,$$

and

$$\frac{1}{2} \left( \text{Var}_t^Q \left[ \sum_{j=1}^{n} s_{t+j} \right] - \text{Var}_t^Q \left[ \sum_{j=1}^{n-1} s_{t+j} \right] \right) = \bar{a}_n - a_n.$$

SRTSM  We start the derivation of equation (6) with the following approximation: $\log (E [e^Z]) \approx E [Z] + \frac{1}{2} \text{Var} [Z]$ for any random variable $Z$. This approximation uses Taylor series expansions for the exponential and natural logarithm functions. For the special case of a Gaussian random variable $Z$, this approximation is exact. Then the forward rate between $t + n$ and $t + n + 1$ can be approximated as follows:

$$f^S_{n,n+1,t} = (n+1)y_{n+1,t} - ny_{nt}$$

$$= -\log \left( e^{-\gamma t} E_t^Q \left[ e^{-\sum_{j=1}^{n} r_{t+j}} \right] \right) + \log \left( e^{-\gamma t} E_t^Q \left[ e^{-\sum_{j=1}^{n-1} r_{t+j}} \right] \right)$$

$$\approx E_t^Q \left[ \sum_{j=1}^{n} r_{t+j} \right] - \frac{1}{2} \text{Var}_t^Q \left[ \sum_{j=1}^{n} r_{t+j} \right] - E_t^Q \left[ \sum_{j=1}^{n-1} r_{t+j} \right] + \frac{1}{2} \text{Var}_t^Q \left[ \sum_{j=1}^{n-1} r_{t+j} \right]$$

$$= E_t^Q [r_{t+n}] - \frac{1}{2} \left( \text{Var}_t^Q \left[ \sum_{j=1}^{n} r_{t+j} \right] - \text{Var}_t^Q \left[ \sum_{j=1}^{n-1} r_{t+j} \right] \right). \quad (A.1)$$
We calculate the first term \( E_t^Q[r_{t+n}] \) analytically:

\[
E_t^Q[r_{t+n}] = E_t^Q[\max (r, s_{t+n})]
\]

\[
= \Pr_t^Q[s_{t+n} < r] \times r + \Pr_t^Q[s_{t+n} \geq r] \times E_t^Q[s_{t+n} | s_{t+n} \geq r]
\]

\[
= r + \sigma_n^Q \left( \frac{\bar{a}_n + b_n'X_t - r}{\sigma_n^Q} \right) \Phi \left( \frac{\bar{a}_n + b_n'X_t - r}{\sigma_n^Q} \right) + \phi \left( \frac{\bar{a}_n + b_n'X_t - r}{\sigma_n^Q} \right)
\]

\[
= r + \sigma_n^Q g \left( \frac{\bar{a}_n + b_n'X_t - r}{\sigma_n^Q} \right). \tag{A.2}
\]

Using the second moments for the truncated normal distribution, we have the following approximations for the conditional variance and covariance (see details in Appendix A.1):

\[
\text{Var}_t^Q[r_{t+n}] \approx \text{Pr}_t^Q[s_{t+n} \geq r] \text{Var}_t^Q[s_{t+n}], \tag{A.3}
\]

\[
\text{Cov}_t^Q[r_{t+n-j}, r_{t+n}] \approx \text{Pr}_t^Q[s_{t+n-j} \geq r, s_{t+n} \geq r] \text{Cov}_t^Q[s_{t+n-j}, s_{t+n}], \forall j = 1, \ldots, n-1. \tag{A.4}
\]

Next, we take the approximation

\[
\Pr_t^Q[s_{t+n-j} \geq r | s_{t+n} \geq r] \approx 1,
\]

using the fact that the shadow rate is very persistent. Equation \(A.4\) becomes

\[
\text{Cov}_t^Q[r_{t+n-j}, r_{t+n}] \approx \text{Pr}_t^Q[s_{t+n} \geq r] \text{Cov}_t^Q[s_{t+n-j}, s_{t+n}].
\]

Then, the second term in equation \(A.1\) is

\[
\frac{1}{2} \left( \text{Var}_t^Q \left[ \sum_{j=1}^{n} r_{t+j} \right] - \text{Var}_t^Q \left[ \sum_{j=1}^{n-1} s_{t+j} \right] \right)
\]

\[
\approx \Pr_t^Q(s_{t+n} \geq r) \times \frac{1}{2} \left( \text{Var}_t^Q \left[ \sum_{j=1}^{n} s_{t+j} \right] - \text{Var}_t^Q \left[ \sum_{j=1}^{n-1} s_{t+j} \right] \right)
\]

\[
= \Phi \left( \frac{\bar{a}_n + b_n'X_t - r}{\sigma_n^Q} \right) \times (a_n - \bar{a}_n). \tag{A.5}
\]

Plug equations \(A.2\) and \(A.5\) to \(A.1\), we conclude our derivation for equation \(6\) with another first-order Taylor approximation:

\[
f_{n,n+1,t}^{SR} \approx r + \sigma_n^Q g \left( \frac{\bar{a}_n + b_n'X_t - r}{\sigma_n^Q} \right) + \Phi \left( \frac{\bar{a}_n + b_n'X_t - r}{\sigma_n^Q} \right) \times (a_n - \bar{a}_n)
\]

\[
= r + \sigma_n^Q g \left( \frac{\bar{a}_n + b_n'X_t - r}{\sigma_n^Q} \right) + \sigma_n^Q \frac{\partial g (\frac{\bar{a}_n + b_n'X_t - r}{\sigma_n^Q})}{\partial a_n} \times (a_n - \bar{a}_n)
\]

\[
\approx r + \sigma_n^Q g \left( \frac{a_n + b_n'X_t - r}{\sigma_n^Q} \right). \tag{A.6}
\]
In the GATSM, the forward rate between $t + n$ and $t + n + 1$ is priced as follows

$$f_{n,n+1,t}^{GA} = (n + 1) y_{n+1,t} - n y_{nt}$$

$$= -\log \left( e^{-s t} \mathbb{E}^Q_t \left[ e^{-\sum_{j=1}^{n-1} s_{t+j}} \right] \right) + \log \left( e^{-s t} \mathbb{E}^Q_t \left[ e^{-\sum_{j=1}^{n-1} s_{t+j}} \right] \right)$$

$$= \mathbb{E}^Q_t \left[ \sum_{j=1}^{n} s_{t+j} \right] - \frac{1}{2} \text{Var}^Q_t \left[ \sum_{j=1}^{n} s_{t+j} \right] - \mathbb{E}^Q_t \left[ \sum_{j=1}^{n-1} s_{t+j} \right] + \frac{1}{2} \text{Var}^Q_t \left[ \sum_{j=1}^{n-1} s_{t+j} \right]$$

$$= \mathbb{E}^Q_t [s_{t+n}] - \frac{1}{2} \left( \text{Var}^Q_t \left[ \sum_{j=1}^{n} s_{t+j} \right] - \text{Var}^Q_t \left[ \sum_{j=1}^{n-1} s_{t+j} \right] \right)$$

$$= \bar{a}_n + b'_n X_t + a_n - \bar{a}_n$$

$$= a_n + b'_n X_t.$$

### Appendix A.1 Approximations to variance and covariance

Define

$$\tilde{s}_{t+n} \equiv \frac{s_{t+n} - \mathbb{E}^Q_t [s_{t+n}]}{\sigma^Q_n} \text{ and } \alpha_{nt} \equiv \frac{r - \mathbb{E}^Q_t [s_{t+n}]}{\sigma^Q_n},$$

then $r_{t+n} = \sigma^Q_n \tilde{r}_{t+n} + \mathbb{E}^Q_t [s_{t+n}]$, where $\tilde{r}_{t+n} \equiv \max (\tilde{s}_{t+n}, \alpha_{nt})$.

**Variance** Standard results for the truncated normal distribution states that if $x \sim N(0, 1)$, then

(i) $\Pr \{ x \geq \alpha \} = 1 - \Phi (\alpha)$, (ii) $\Pr \{ x \geq \alpha \} \mathbb{E} \{ xx \geq \alpha \} = \phi (\alpha)$, and (iii)$\Pr \{ x \geq \alpha \} \mathbb{E} \{ x^2 \mid x \geq \alpha \} = 1 - \Phi (\alpha) + \alpha \phi (\alpha)$. Since $\tilde{s}_{t+n}$ is conditionally normally distributed with mean 0 and variance 1 under the Q measure,

$$\mathbb{E}^Q_t [\tilde{s}_{t+n}] = \Pr^Q_t [\tilde{s}_{t+n} \geq \alpha_{nt}] \mathbb{E}^Q_t [\tilde{s}_{t+n} | \tilde{s}_{t+n} \geq \alpha_{nt}] + \Pr^Q_t [\tilde{s}_{t+n} < \alpha_{nt}] \alpha_{nt}$$

$$= \phi (\alpha_{nt}) + \alpha_{nt} \Phi (\alpha_{nt}),$$

$$\mathbb{E}^Q_t [\tilde{r}_{t+n}^2] = \Pr^Q_t [\tilde{s}_{t+n} \geq \alpha_{nt}] \mathbb{E}^Q_t [\tilde{s}_{t+n}^2 | \tilde{s}_{t+n} \geq \alpha_{nt}] + \Pr^Q_t [\tilde{s}_{t+n} < \alpha_{nt}] \alpha_{nt}^2$$

$$= 1 - \Phi (\alpha_{nt}) + \alpha_{nt} \phi (\alpha_{nt}) + \alpha_{nt}^2 \Phi (\alpha_{nt}).$$

Accordingly,

$$\text{Var}^Q_t [r_{t+n}] = (\sigma^Q_n)^2 \text{Var}^Q_t [\tilde{r}_{t+n}] = (\sigma^Q_n)^2 \left( \mathbb{E}^Q_t [\tilde{r}_{t+n}^2] - (\mathbb{E}^Q_t [\tilde{r}_{t+n}])^2 \right)$$

$$= (\sigma^Q_n)^2 \left( 1 - \Phi (\alpha_{nt}) + \alpha_{nt} \phi (\alpha_{nt}) + \alpha_{nt}^2 \Phi (\alpha_{nt}) - (\phi (\alpha_{nt}) + \alpha_{nt} \Phi (\alpha_{nt}))^2 \right).$$

Comparing the exact formula in equation [A.8] with the approximation in equation [A.3], or

$$\text{Var}^Q_t (r_{t+n}) \approx \Pr^Q_t [s_{t+n} \geq r] \text{Var}^Q_t [s_{t+n}] = \left( \sigma^Q_n \right)^2 (1 - \Phi (\alpha_{nt})),$$

the approximation error is

$$\left( \sigma^Q_n \right)^2 \left\{ (1 - \Phi (\alpha_{nt}) + \alpha_{nt} \phi (\alpha_{nt}) + \alpha_{nt}^2 \Phi (\alpha_{nt}) - (\phi (\alpha_{nt}) + \alpha_{nt} \Phi (\alpha_{nt}))^2 \right) - (1 - \Phi (\alpha_{nt})) \right)$$

$$= -\left( \sigma^Q_n \right)^2 g (\alpha_{nt}) g (-\alpha_{nt}) \equiv \left( \sigma^Q_n \right)^2 D (\alpha_{nt}).$$
The first derivative of $D(\alpha_{nt})$ is $D'(\alpha_{nt}) = -g'(\alpha_{nt}) g(-\alpha_{nt}) + g(\alpha_{nt}) g'(-\alpha_{nt})$, and $D'(\alpha_{nt}) |_{\alpha_{nt}=0} = 0$. Therefore $D(0)$ is a local maximum/minimum. From Figure A.1 $D(.)$ is bounded by 0 from above and achieves the global minimum at $\alpha_{nt} = 0$. Therefore, the absolute approximation error is bounded by a small number $(\sigma_n^Q)^2 \phi(0)^2$.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure_a1}
\caption{$D(\alpha_{nt})$}
\end{figure}

**Covariance** Standard results for the multivariate truncated normal distribution states that if 
\[ [x_1, x_2] \sim N \left( \begin{bmatrix} 0 \\ 0 \end{bmatrix}, \begin{bmatrix} 1 & \rho \\ \rho & 1 \end{bmatrix} \right), \]
then
\begin{enumerate}
  \item $\Pr [x_1|x_1 ≥ \alpha_1, x_2 ≥ \alpha_2] = F(-\alpha_1, -\alpha_2; \rho)$,
  \item $\Pr [x_1|x_1 ≥ \alpha_1, x_2 ≥ \alpha_2] E [x_1|x_1 ≥ \alpha_1, x_2 ≥ \alpha_2] = h(\alpha_1, \alpha_2, \rho) + \rho h(\alpha_2, \alpha_1, \rho)$,
  \item $\Pr [x_1|x_1 ≥ \alpha_1, x_2 ≥ \alpha_2] E [x_1|x_1 ≥ \alpha_1, x_2 ≥ \alpha_2]$
  \[ = \rho (\alpha_1 h(\alpha_1, \alpha_2; \rho) + \alpha_2 h(\alpha_2, \alpha_1; \rho) + F(-\alpha_1, -\alpha_2; \rho)) + (1 - \rho^2) f(\alpha_1, \alpha_2; \rho), \]
\end{enumerate}

where
\begin{align*}
  f(x_1, x_2; \rho) &\equiv \lambda (2\pi)^{-1} \exp \left\{ -\frac{1}{2} \lambda^2 (x_1^2 - 2\rho x_1 x_2 + x_2^2) \right\}, \\
  F(\alpha_1, \alpha_2; \rho) &\equiv \int_{-\infty}^{\alpha_1} \int_{-\infty}^{\alpha_2} f(x_1, x_2; \rho) dx_1 dx_2, \\
  h(\alpha_1, \alpha_2; \rho) &\equiv \phi(\alpha_1) \Phi (\lambda (\rho \alpha_1 - \alpha_2)), \\
  \lambda &\equiv (1 - \rho^2)^{-\frac{1}{2}}.
\end{align*}
Let $\rho_{mnt}$ be the correlation between $\tilde{s}_{t+m}$ and $\tilde{s}_{t+n}$ under the $Q$ measure, then,

\[
E_t^Q [\tilde{r}_{t+m} \tilde{r}_{t+n}] = E_t^Q [\tilde{s}_{t+m} \tilde{s}_{t+n} | \tilde{s}_{t+m} \geq \alpha_{mt}, \tilde{s}_{t+n} \geq \alpha_{nt}] P_{t}^Q (\tilde{s}_{t+m} \geq \alpha_{mt}, \tilde{s}_{t+n} \geq \alpha_{nt})
\]

\[+ \alpha_{mt} E_t^Q [\tilde{s}_{t+m} | \tilde{s}_{t+m} < \alpha_{mt}, \tilde{s}_{t+n} \geq \alpha_{nt}] P_{t}^Q (\tilde{s}_{t+m} < \alpha_{mt}, \tilde{s}_{t+n} \geq \alpha_{nt})
\]

\[+ \alpha_{nt} E_t^Q [\tilde{s}_{t+n} | \tilde{s}_{t+n} \geq \alpha_{mt}, \tilde{s}_{t+n} < \alpha_{nt}] P_{t}^Q (\tilde{s}_{t+m} \geq \alpha_{mt}, \tilde{s}_{t+n} < \alpha_{nt})
\]

\[+ \alpha_{mt} \alpha_{nt} P_{t}^Q (\tilde{s}_{t+m} < \alpha_{mt}, \tilde{s}_{t+n} < \alpha_{nt})
\]

\[\quad = \rho_{mnt} (\alpha_{mt} h(\alpha_{mt}, \alpha_{nt}; \rho_{mnt}) + \alpha_{mt} h(\alpha_{nt}, \alpha_{mt}; \rho_{mnt}) + F(-\alpha_{mt}, -\alpha_{nt}; \rho_{mnt}))
\]

\[+ (1 - \rho_{mnt}^2) f(\alpha_{mt}, \alpha_{nt}; \rho_{mnt})
\]

\[+ \alpha_{mt} h(\alpha_{nt}, -\alpha_{mt}; -\rho_{mnt}) - \rho_{mnt} h(-\alpha_{mt}, \alpha_{nt}; -\rho_{mnt})
\]

\[+ \alpha_{nt} h(\alpha_{nt}, -\alpha_{nt}; -\rho_{mnt}) - \rho_{mnt} h(-\alpha_{nt}, \alpha_{nt}; -\rho_{mnt})
\]

\[+ \alpha_{mt} \alpha_{nt} F(\alpha_{mt}, \alpha_{nt}; \rho_{mnt}).
\]

With the identity $h(\alpha_1, \alpha_2; \rho) = h(-\alpha_1, \alpha_2; -\rho)$, we simplify the expression above as follows:

\[
E_t^Q [\tilde{r}_{t+m} \tilde{r}_{t+n}] = \rho_{mnt} F(-\alpha_{mt}, -\alpha_{nt}; \rho_{mnt}) + (1 - \rho_{mnt}^2) f(\alpha_{mt}, \alpha_{nt}; \rho_{mnt})
\]

\[+ \alpha_{mt} h(\alpha_{nt}, -\alpha_{mt}; -\rho_{mnt}) + \alpha_{nt} h(\alpha_{nt}, -\alpha_{nt}; -\rho_{mnt}) + \alpha_{mt} \alpha_{nt} F(\alpha_{mt}, \alpha_{nt}; \rho_{mnt}).
\]

From equation (A.7), we have

\[
E_t^Q [\tilde{r}_{t+m}] E_t^Q [\tilde{r}_{t+n}] = \left( \phi(\alpha_{mt}) + \alpha_{mt} \Phi(\alpha_{mt}) \right) \left( \phi(\alpha_{nt}) + \alpha_{nt} \Phi(\alpha_{nt}) \right).
\]

Accordingly,

\[
Cov_t^Q [\tilde{r}_{t+m}, \tilde{r}_{t+n}] = \sigma_m^Q \sigma_n^Q Cov_t^Q [\tilde{r}_{t+m}, \tilde{r}_{t+n}]
\]

\[= \sigma_m^Q \sigma_n^Q \left( E_t^Q [\tilde{r}_{t+m} \tilde{r}_{t+n}] - E_t^Q [\tilde{r}_{t+m}] E_t^Q [\tilde{r}_{t+n}] \right).
\]

Comparing the exact formula in equation (A.9) with the approximation in equation (A.4), or

\[
Cov_t^Q [\tilde{r}_{t+m}, \tilde{r}_{t+n}] \approx Pr_t^Q [\tilde{s}_{t+m} \geq r, \tilde{s}_{t+n} \geq r] Cov_t^Q [\tilde{s}_{t+m}, \tilde{s}_{t+n}] = \rho_{mnt} \sigma_m^Q \sigma_n^Q F(-\alpha_{mt}, -\alpha_{nt}; \rho_{mnt}),
\]

the approximation error is

\[
\sigma_m^Q \sigma_n^Q \times \left\{ (1 - \rho_{mnt}^2) f(\alpha_{mt}, \alpha_{nt}; \rho_{mnt}) + \alpha_{mt} h(\alpha_{nt}, -\alpha_{mt}; -\rho_{mnt}) + \alpha_{nt} h(\alpha_{nt}, -\alpha_{nt}; -\rho_{mnt})
\]

\[+ \alpha_{mt} \alpha_{nt} F(\alpha_{mt}, \alpha_{nt}; \rho_{mnt}) - \phi(\alpha_{mt}) + \alpha_{mt} \Phi(\alpha_{mt}) \right) \left( \phi(\alpha_{nt}) + \alpha_{nt} \Phi(\alpha_{nt}) \right) \}
\]

\[\equiv \sigma_m^Q \sigma_n^Q D(\alpha_{mt}, \alpha_{nt}; \rho_{mnt}).
\]

The first derivative of $D(\alpha_{mt}, \alpha_{nt}; \rho_{mnt})$ with respect to $\alpha_{mt}$ is

\[
\frac{\partial D(\alpha_{mt}, \alpha_{nt}; \rho_{mnt})}{\partial \alpha_{mt}} = - (\alpha_{mt} - \rho \alpha_{nt}) f(\alpha_{mt}, \alpha_{nt}; \rho_{mnt})
\]

\[+ h(\alpha_{nt}, -\alpha_{mt}; -\rho_{mnt}) + \lambda_{mnt} \alpha_{nt} \phi(\alpha_{nt}) \phi(\lambda_{mnt} (-\rho_{mnt} \alpha_{nt} + \alpha_{nt}))
\]

\[- \alpha_{nt} \alpha_{nt} \Phi(\alpha_{mt}) \phi(\lambda_{mnt} (-\rho_{mnt} \alpha_{nt} + \alpha_{nt}))
\]

\[- \lambda_{mnt} \rho_{mnt} \alpha_{nt} \phi(\alpha_{nt}) \phi(\lambda_{mnt} (-\rho_{mnt} \alpha_{nt} + \alpha_{nt}))
\]

\[+ \alpha_{nt} F(\alpha_{mt}, \alpha_{nt}; \rho_{mnt}) + \alpha_{mt} \alpha_{nt} h(\alpha_{mt}, -\alpha_{nt}; -\rho_{mnt})
\]

\[- \Phi(\alpha_{mt}) \phi(\alpha_{nt}) + \alpha_{nt} \Phi(\alpha_{nt}).
\]
where and \( \lambda_{mnt} = (1 - \rho_{mnt}^2)^{-\frac{1}{2}} \), and \( \frac{\partial D(\alpha_{mt},\alpha_{nt};\rho_{mnt})}{\partial \alpha_{mnt}}|_{\alpha_{mnt}=0,\alpha_{nt}=0} = \phi(0) \Phi(0) - \phi(0) \Phi(0) = 0 \).

Since \( D(\alpha_{mt},\alpha_{nt};\rho_{mnt}) = D(\alpha_{nt},\alpha_{mt};\rho_{mnt}) \), we have \( \frac{\partial D(\alpha_{mt},\alpha_{nt};\rho_{mnt})}{\partial \alpha_{nt}}|_{\alpha_{mnt}=0,\alpha_{nt}=0} = 0 \) as well. Thus, \( D(0,0;\rho_{mnt}) \) is a local maximum/minimum. We plot \( D(\alpha_{mt},\alpha_{nt};\rho_{mnt}) \) for \( \rho = -0.9, -0.8, ..., 0.8, 0.9 \) in Figure A.2 and \( D(\alpha_{mt},\alpha_{nt};\rho) \) is bounded by 0 from above and achieves the global minimum at \( \alpha_{mnt} = 0, \alpha_{nt} = 0 \). Therefore, the absolute approximation error is bounded by a small number, \( \sigma_{Q}^2\sigma_{Q'}^2\left(1 - (1 - \rho^2)^{\frac{1}{2}}\right) \phi^2(0) \).

![Figure A.2: \( D(\alpha_{mt},\alpha_{nt};\rho_{mnt}) \)][1]

**Appendix B  Kalman filters**

**Extended Kalman filter for the SRTSM**  The transition equation is in (3). Stack the observation equation in (10) for all 7 maturities, we get the following system:

\[
F_{t+1} = G(X_{t+1}) + \eta_{t+1}^{SR} \quad \eta_{t+1}^{SR} \sim N(0, \omega_{SR}I_7).
\]

Approximate the conditional distribution of \( X_t \) with \( X_t|F_{t+1} \sim N(\hat{X}_{t+1|t}, P_{t+1|t}) \). Update \( \hat{X}_{t+1|t+1} \) and \( P_{t+1|t+1} \) as follows:

\[
\begin{align*}
\hat{X}_{t+1|t+1} &= \hat{X}_{t+1|t} + K_{t+1}(F_{t+1} - \hat{F}_{t+1|t}), \\
P_{t+1|t+1} &= H_{t+1}P_{t+1|t}H_{t+1} + \omega_{SR}I_7, \\
\dot{X}_{t+1|t} &= \mu + \rho \dot{X}_{t|t}, \\
P_{t+1|t} &= \rho P_{t|t} + \Sigma', 
\end{align*}
\]

---

[1]: Figure A.2: \( D(\alpha_{mt},\alpha_{nt};\rho_{mnt}) \)
with the matrices defined as
\[
\hat{F}_{t+1|t} = G(\hat{X}_{t+1|t}), \\
H_{t+1} = \left. \frac{\partial G(X_{t+1})}{\partial X_{t+1}'(\hat{X}_{t+1|t})} \right|_{X_{t+1}=\hat{X}_{t+1|t}} , \\
K_{t+1} = P_{t+1|t}H_{t+1}^{-1}(H_{t+1}'P_{t+1|t}H_{t+1} + \omega_{SR}I_7)^{-1} ,
\]
where we can obtain \( H_{t+1} \) by stacking \( \Phi \left( \frac{a_n + b_n'X_{t+1|t}}{\sigma_n^2} \right) \times b_n' \) for the 7 maturities. Given the initial values \( \hat{X}_{0|0} \) and \( P_{0|0} \), we can update \( \{\hat{X}_{t|t}, P_{t|t}\}_{t=1}^T \) recursively with the above algorithm. The log likelihood is
\[
L^{SR} = \frac{-7T}{2} \log 2\pi - \frac{1}{2} \sum_{t=1}^T \log |H_{t}'P_{t+1|t}H_{t} + \omega_{SR}I_7| \\
- \frac{1}{2} \sum_{t=1}^T (\hat{F}_{t} - G(\hat{X}_{t|t-1}))' (H_{t}'P_{t+1|t}H_{t} + \omega_{SR}I_7)^{-1} (\hat{F}_{t} - h(\hat{X}_{t|t-1})).
\]

**Kalman filter for the GATSM** The GATSM is a linear Gaussian state space model. The \( G(.) \) function stacks the linear function in equation (11). The matrix \( H_{t+1} \) stacks \( b_n' \) for the 7 maturities. The algorithm described above collapses to a Kalman filter.

**Appendix C  Factor construction for the FAVAR**

This appendix illustrates how to construct the macro factors. First, extract the first 3 principal components \( \hat{p}c_t \) from \( Y_t^m \). Then extract first 3 principal components \( \hat{p}c_t^* \) from the slowing-moving variables indicated with “*” in Table 3. Normalize them to unit variance. Next, run the following regression \( \hat{p}c_t = b_{pc}\hat{p}c_t^* + b_{pc,s}t + \eta_t^p \) and construct \( \hat{x}_t^m \) from \( \hat{p}c_t - \hat{b}_{pc,s}t \). We then estimate equation (13) as follows. If \( Y_t^{m,i} \) is among the slow-moving variables, we regress \( Y_t^{m,i} \) on a constant and \( \hat{x}_t^m \) to obtain \( \hat{a}_{m,i} \) and \( \hat{b}_{x,i} \) and set \( \hat{b}_{s,i} = 0 \). For other variables, we regress \( Y_t^{m,i} \) on a constant, \( \hat{x}_t^m \) and \( s_t^p \) to get \( \hat{a}_{m,i} \), \( \hat{b}_{x,i} \) and \( \hat{b}_{s,i} \).
Blue curve: function $g(z) = z\Phi(z) + \phi(z)$. Red line: 45-degree line.

One-month forward rates (annualized) monthly from January 1990 to June 2013. Maturities are 3 and 6 months, 1, 2, 5, 7 and 10 years. The gray area marks the ZLB period from December 2008 to June 2013.
Figure 3: Observed and fitted forward curves

Average forward curves in 2012. Blue curves: fitted forward curves, from the SRTSM in the left panel and the GATSM in the right panel. Red dots: observed data. X-axis: maturity in years.

Figure 4: The shadow rate and effective federal funds rate

Blue line: the estimated shadow rate of the SRTSM from January 1990 to June 2013. Green line: the effective federal funds rate. Black line: lower bound $r$. The gray area marks the ZLB period from December 2008 to June 2013.
Figure 5: Loadings on the macroeconomic factors and policy rate

Loadings of standardized economic variables $Y_{i,m}$ on the three macroeconomic factors and the standardized policy rate. X-axis: identification number for economic variables in Table 3.

Figure 6: Observed and counterfactual macroeconomic variables

Blue lines: observed economic variables. Red dashed lines: what would happen to these macroeconomic variables, if all the monetary policy shocks at the ZLB (July 2009 - May 2013) were shut down.
Figure 7: Impulse responses with full sample

Impulse responses to a -25 basis-point shock on monetary policy. 90% confidence intervals are shaded. Sample: January 1960 - May 2013. Model: FAVAR with 3 macro factors and 13 lags. X-axis: response time in months. The policy rate is measured in annualized percentage; the industrial production index, consumer price index and housing starts are measured in percentage deviation from the steady state; the capacity utilization and unemployment rate are measured in percentage point.
Impulse responses to a -25 basis-point shock on monetary policy. 90% confidence intervals are shaded. Blue: full sample from January 1960 to May 2013 with the policy rate in FAVAR (13). Turquoise: ZLB from July 2009 to May 2013 with the effective federal funds rate in FAVAR (1). X-axis: response time in months. The policy rate is measured in annualized percentage; the industrial production index, consumer price index and housing starts are measured in percentage deviation from the steady state; the capacity utilization and unemployment rate are measured in percentage point.
Figure 9: Impulse responses (full sample vs. ZLB with new policy rate)

Impulse responses to a -25 basis-point shock on monetary policy. 90% confidence intervals are shaded. Blue: full sample from January 1960 to May 2013 with the policy rate in FAVAR (13). Turquoise: ZLB from July 2009 to May 2013 with the policy rate in a FAVAR (1). X-axis: response time in months. The policy rate is measured in annualized percentage; the industrial production index, consumer price index and housing starts are measured in percentage deviation from the steady state; the capacity utilization and unemployment rate are measured in percentage point.
Blue triangles: the market’s expected lift-off dates from January 2009 to June 2013. Four green vertical lines mark the following months when forward guidance specified explicit lift-off dates for the ZLB: August 2011, January 2012, September 2012 and June 2013. The corresponding lift-off dates are in red triangle. Black dashed line: 45 degree line.
Figure 11: Impulse responses (ZLB with expected duration)

Impulse responses to a one year shock to expected ZLB duration. 90% confidence intervals are shaded. Sample: ZLB from July 2009 to May 2013. Model: FAVAR (1) with the ZLB duration as the monetary policy measure. X-axis: response time in months. The expected duration is measured in year; the industrial production index, consumer price index and housing starts are measured in percentage deviation from the steady state; the capacity utilization and unemployment rate are measured in percentage point.
Figure 12: Impulse responses at ZLB (policy rate v.s. ZLB duration)

Turquoise: impulse responses to a -35 basis-point shock on the policy rate. Blue: impulse responses to a one year shock on the ZLB duration. 90% confidence intervals are shaded. Sample: ZLB from July 2009 to May 2013. Model: FAVAR (1). X-axis: response time in months. The policy rate is measured in -35 basis points; the expected duration is measured in year; the industrial production index, consumer price index and housing starts are measured in percentage deviation from the steady state; the capacity utilization and unemployment rate are measured in percentage point.

</table>

Differences in forward rates and yields implied by equation (6) and by simulation for the 24 Januaries between 1990 and 2013. At time $t$, we simulate 10 million paths of $s_{t+j}$ for $j = 1, ..., 120$ with the estimated factors $X_t$ and $Q$ parameters, and compute $r_{t+j}$ based on equation (1). Then we compute the corresponding 10 million $y_{nt} = -\frac{1}{n} \log \left( E^Q_t \left[ \exp(-r_t - r_{t+1} - ... - r_{t+n-1}) \right] \right)$ and $f_{n,n+1,t} = (n+1)y_{n+1,t} - ny_{nt}$. We take the average of the 10 million draws as the simulated yield or forward rate. All numbers are measured in basis points.

<tbody>
<tr>
<td>12/16/2008</td>
<td>“...anticipates that weak economic conditions are likely to warrant exceptionally low levels of the federal funds rate for some time.”</td>
</tr>
<tr>
<td>03/18/2009</td>
<td>“...anticipates that economic conditions are likely to warrant exceptionally low levels of the federal funds rate for an extended period.”</td>
</tr>
<tr>
<td>08/09/2011*</td>
<td>“...anticipates that economic conditions—including low rates of resource utilization and a subdued outlook for inflation over the medium run—are likely to warrant exceptionally low levels for the federal funds rate at least through mid-2013.”</td>
</tr>
<tr>
<td>01/25/2012*</td>
<td>“...decided today to keep the target range for the federal funds rate at 0 to 1/4 percent and currently anticipates that economic conditions—including low rates of resource utilization and a subdued outlook for inflation over the medium run—are likely to warrant exceptionally low levels for the federal funds rate at least through late 2014.”</td>
</tr>
<tr>
<td>09/13/2012*</td>
<td>“...decided today to keep the target range for the federal funds rate at 0 to 1/4 percent and currently anticipates that exceptionally low levels for the federal funds rate are likely to be warranted at least through mid-2015.”</td>
</tr>
<tr>
<td>12/12/2012</td>
<td>“...decided to keep the target range for the federal funds rate at 0 to 1/4 percent and currently anticipates that this exceptionally low range for the federal funds rate will be appropriate at least as long as the unemployment rate remains above 6-1/2 percent, inflation between one and two years ahead is projected to be no more than a half percentage point above the Committee’s 2 percent longer-run goal, and longer-term inflation expectations continue to be well anchored.”</td>
</tr>
<tr>
<td>06/19/2013*</td>
<td>“...14 of 19 FOMC participants indicated that they expect the first increase in the target for the federal funds rate to occur in 2015, and one expected the first increase to incur in 2016.”</td>
</tr>
</tbody>
</table>

This table summarizes a list of forward guidance quotes, when the Fed expected a different lift-off date or condition for the ZLB. All quotes except the last one are from FOMC statements. The last quote is from Chairman Bernanke’s press conference. Asterisks mark the statements with explicit lift-off dates, with the corresponding lift-off dates in red.
